OOP

Gavrilut Dragos Course 5

Summary

- Inheritance
- Virtual methods
- ► How virtual methods are modeled by C++ compiler
- Covariance
- Abstract classes (Interfaces)
- Memory alignment in case of inheritance

- Inheritance is a process that transfer class proprieties (methods and members) from one class (often called the base class to another that inherits the base class called derived class). The derive class may extend the base class by adding additional methods and/or members.
- Such an example will be the class Automobile, where we can define the following properties:
 - Number of doors
 - Number of wheels
 - Size
- From this class we can derive a particularization of the Automobile class (for example electrical machines) that besides the properties of the base class (doors, wheels, size, etc) has it's own properties (battery life time).

- ▶ Inheritance in case of C++ classes can be simple or multiple:
 - Simple Inheritance

```
Simple
class <class_name>: <access modifier> <base class> { ... }
```

Multiple Inheritance

- The access modifier is optional and can be one of the following: (public / private or protected).
- ▶ If it is not specified, the default access modifier is private.

► Class "Derived" inherits members and methods from class "Base". That is why we can call methods SetX and SetY from an instance of "Derived" class.

```
class Base
public:
     int x;
     void SetX(int value);
class Derived : public Base
     int y;
public:
      void SetY(int value);
};
void main()
     Derived d;
     d.SetX(100);
     d.x = 10;
     d.SetY(200);
```

The following code will not compile. Class "Derived" inherits class "Base", but member "x" from class Base is private (this means that it can not be accessed in class "Derived").

```
class Base
private:
     int x;
class Derived : public Base
     int y;
public:
     void SetY(int value);
     void SetX(int value);
};
void Derived::SetX(int value)
                                error C2248: 'Base::x': cannot access private member declared
                                in class 'Base'
     x = value;
                                note: see declaration of 'Base::x'
                                note: see declaration of 'Base'
void main()
     Derived d;
     d.SetX(100);
     d.SetY(200);
```

The solution for this case is to use the "protected" access modifier. A protected member is a member that can be access by classes that inherits current class, but it can not be accessed from outside the class.

```
class Base
protected:
      int x;
class Derived : public Base
      int y;
public:
      void SetY(int value);
      void SetX(int value);
};
void Derived::SetX(int value)
      x = value;
void main()
      Derived d;
      d.SetX(100);
      d.SetY(200);
```

The code below will not compile. "x" is declared as *protected* - this means that it can be accessed in method *SetX* from a derived class, but it can not be accessed outside it's scope (class).

```
class Base
protected:
     int x;
class Derived : public Base
     int y;
public:
      void SetY(int value);
     void SetX(int value);
};
void Derived::SetX(int value)
     x = value;
void main()
     Derived d;
                              error C2248: 'Base::x': cannot access protected member declared
     d.SetX(100);
                              in class 'Base'
     d.x = 100;
                              note: see declaration of 'Base::x'
                              note: see declaration of 'Base'
```

The following table shows if a member with a specific access modifier can be access and in what conditions:

Access modifier	In the same class	In a derived class	Outside it's scope	Friend function in the base class	Friend function in the derived class
public	Yes	Yes	Yes	Yes	Yes
protected	Yes	Yes	No	Yes	Yes
private	Yes	No	No	Yes	No

App.cpp

Derived d; SetX(d);

The code below will not compile. "x" is a private member of "Base" therefor a friend function defined in "Derived" class can not access it.

class Base { private: int x; }; class Derived : public Base { int y; public: void SetY(int value); void friend SetX(Derived &d); }; void SetX(Derived &d) { d.x = 100; } void main()

The solution is to change the access modifier of data member "x" from class "Base" from private to protected.

```
class Base
protected:
     int x;
class Derived : public Base
     int y;
public:
      void SetY(int value);
     void friend SetX(Derived &d);
};
void SetX(Derived &d)
      d.x = 100;
void main()
     Derived d;
      SetX(d);
```

▶ Be careful where you define the friend function. In the example below SetX friend function is declared in the "Derived" class. This means that it can access methods and data members from instances of "Derived" class and not other classes (e.g. Base class). The code will not compile.

```
class Base
private:
      int x;
class Derived : public Base
     int y;
public:
     void SetV(int value).
     void friend SetX(Base &d);
void SetX(Base &d)
      d.x = 100;
void main()
      Derived d;
```

This code will work properly because the friend function is defined in class "Base".

```
class Base
private:
     int x;
public:
     void friend SetX(Base &d);
class Derived : public Base
     int y;
public:
     void SetY(int value);
void SetX(Base &d)
      d.x = 100;
void main()
     Derived d;
```

- Access modifiers can also be applied to the inheritance relation.
- As a result, the members from the base class change their original access modifier in the derived class.

App.cpp class Base { public: int x; }; class Derived : public Base { int y; public: void SetY(int value) { ... } }; void main() { Derived d; d.x = 100; }

In this case, because "x" is public in the "Base" class, and the inheritance relation is also public, "x" will be public as well in the "Derived" class and will be accessible from outside the class scope.

- Access modifiers can also be applied to the inheritance relation.
- As a result, the members from the base class change their original access modifier in the derived class.

App.cpp class Base { public: int x; }; class Derived : private Base { int y; public: void SetY(int value) { ... } }; void main() { Derived d; d.x = 100; }

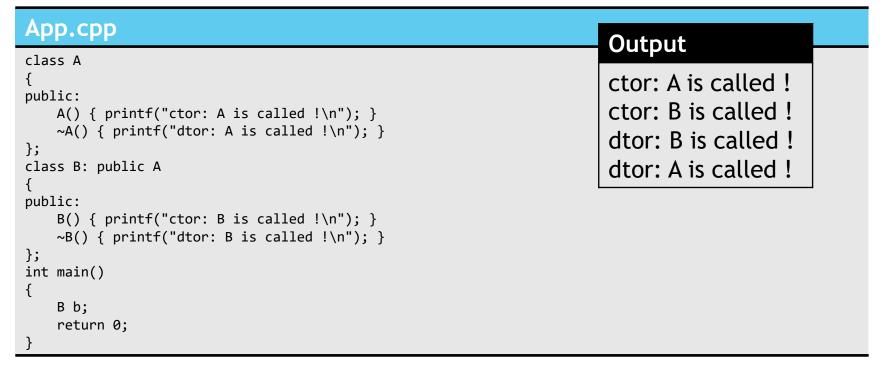

- This code will not compile. "x" is indeed public in class "Base", but since the inherit relation between class "Base" and class "Derived" is private, "x" will change its access modifier from public to private in class Derived and will not be accessible from outside its scope.
- However, if we are to create an instance of type "Base" we will be able to access "x" for that instance outside its scope.

The rules that show how an access modifier is change if we change the access modifier of the inheritance relation are as follows:

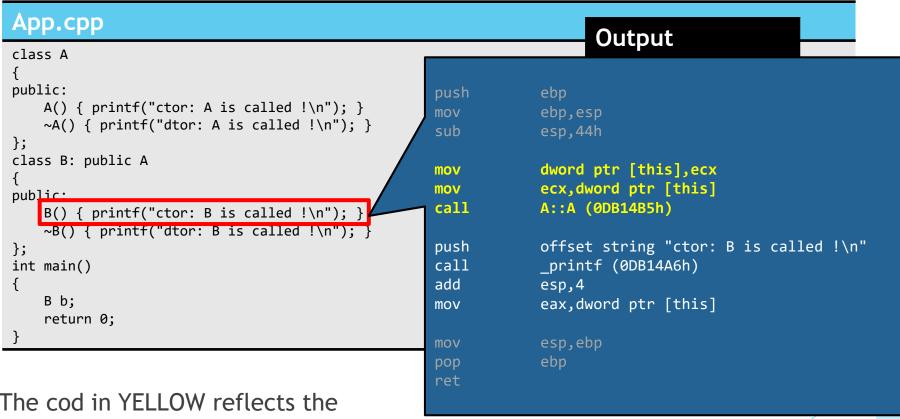

Access modifier used for the inheritance relation	public	private	protected	
Access modifier used for a data member or method				
public	public	private	protected	
private	private	private	private	
protected	protected	private	protected	

private > protected > public

Let's consider the following case:

Let's consider the following case:

The cod in YELLOW reflects the execution of the base constructor.

Let's consider the following case:

```
App.cpp
                                                                    Output
class A
                                                                    ctor: B is called!
public:
   A() { printf("ctor: A is called !\n"); }
                                                                    ctor: A is called!
   ~A() { printf("dtor: A is called !\n"); }
                                                                    ctor: C is called!
class B
                                                                    dtor: C is called!
                                                                    dtor: A is called!
public:
   B() { printf("ctor: B is called !\n"); }
                                                                    dtor: B is called!
   ~B() { printf("dtor: B is called !\n"); }
class C: public B, public A
public:
   C() { printf("ctor: C is called !\n"); }
   ~C() { printf("dtor: C is called !\n"); }
int main() {
   C C;
   return 0;
```

In case of multiple inheritance, the order of base classes is used when the constructor is called (in this case - first class B, then class A and finally class C)

Let's consider the following case:

```
App.cpp
                                                                     Output
class A
                                                                     ctor: B is called!
public:
   A() { printf("ctor: A is called !\n"); }
                                                                     ctor: A is called!
   ~A() { printf("dtor: A is called !\n"); }
                                                                     dtor: A is called!
class B
                                                                     dtor: B is called!
public:
   B() { printf("ctor: B is called !\n"); }
   ~B() { printf("dtor: B is called !\n"); }
class C: public B, public A
public:
int main() {
   C c;
   return 0;
```

If no constructor is defined in class C, but there are at least one constructor defined in one of the class from witch C is derived from, the compiler will create a default constructor that calls the constructor of class B followed by the constructor of class A.

Let's consider the following case:

```
App.cpp
class A
public:
   A(int x) { printf("ctor: A is called !\n"); }
   ~A() { printf("dtor: A is called !\n"); }
class B
public:
   B() { printf("ctor: B is called !\n"); }
   ~B() { printf("dtor: B is called !\n"); }
class C: public B, public A
public:
                             error C2280: 'C::C(void)': attempting to reference a deleted function
};
                             note: compiler has generated 'C::C' here
int main() 
                             note: 'C::C(void)': function was implicitly deleted because a base class
 Cc;
                              'A' has either no appropriate default constructor or overload resolution
   return 0;
                             was ambiguous
                              note: see declaration of 'A'
```

This code will fail, as there is no explicit call to A::A(int) constructor.

Let's consider the following case:

```
App.cpp
                                                                     Output
class A
                                                                    ctor: B is called!
public:
   A(int x) { printf("ctor: A is called !\n"); }
                                                                    ctor: A is called!
   ~A() { printf("dtor: A is called !\n"); }
                                                                    ctor: C is called!
class B
                                                                    dtor: C is called!
                                                                    dtor: A is called!
public:
   B() { printf("ctor: B is called !\n"); }
                                                                    dtor: B is called!
   ~B() { printf("dtor: B is called !\n"); }
class C: public B, public A
public:
   C() : A(100) { printf("ctor: C is called !\n"); }
   ~C() { printf("dtor: C is called !\n"); }
int main() {
   C c;
   return 0;
```

The solution is to explicitly call the constructor of A in the member initializer list for C::C()

Let's consider the following case:

App.cpp class A public: A(int x) { printf("ctor: A is called !\n"); } ~A() { printf("dtor: A is called !\n"); } class B public: B() { printf("ctor: B is called !\n"); } ~B() { printf("dtor: B is called !\n"); } class C: public B, public A public: C() : A(100), B() { printf("ctor: C is called !\n"); } ~C() { printf("dtor: C is called !\n"); } int main() { C C; return 0;

Output

ctor: B is called! ctor: A is called! ctor: C is called! dtor: C is called! dtor: A is called! dtor: B is called!

Using this method WILL NOT CHANGE the order of the constructors (in this case, even if we call A(100) followed by B(), the compiler will still call B::B() first and then A::A(int)

Let's consider the following case:

App.cpp class A { public: A(int x) { printf("ctor: A is called !\n"); } ~A() { printf("dtor: A is called !\n"); } class B { public: B() { printf("ctor: B is called !\n"); } ~B() { printf("dtor: B is called !\n"); } **}**; class C { public: C(bool n) { printf("ctor: C is called !\n"); } ~C() { printf("dtor: C is called !\n"); } **}**; class D: public B, public A **C** c; public: D(): c(true), A(100),B() { printf("ctor: D is called !\n"); } ~D() { printf("dtor: D is called !\n"); } **}**; int main() { D d; return 0;

Output

ctor: B is called!
ctor: A is called!
ctor: C is called!
ctor: D is called!
dtor: D is called!
dtor: C is called!
dtor: A is called!
dtor: B is called!

Let's consider the following case:

App.cpp ctor: B is called! struct A { ctor: A is called! A(int x) { printf("ctor: A is called !\n"); } ~A() { printf("dtor: A is called !\n"); } ctor: C is called! **}**; ctor: D is called! struct B { B() { printf("ctor: B is called !\n"); } -- v2 is initialized ~B() { printf("dtor: B is called !\n"); } **}**; -- v1 is initialized struct C { ctor: E is called! C(bool n) { printf("ctor: C is called !\n"); } ~C() { printf("dtor: C is called !\n"); } dtor: E is called! **}**; dtor: D is called! struct D { D(bool n) { printf("ctor: D is called !\n"); } dtor: C is called! ~D() { printf("dtor: D is called !\n"); } dtor: A is called! class E: public B, public A { dtor: B is called! C c; D d; int v1, v2; public: E(): d(true), A(100), c(true), B(), v2(100), v1(20) { printf("ctor: E is called !\n"); } ~E() { printf("dtor: E is called !\n"); } **}**; void main() { E e;

Output

- When inheriting from multiple classes, the general rule for calling constructors and destructors is as follows:
- 1. First all of the constructors from the base classes are called in the order of their inheriting definition (left-to-right)
- 2. All of the constructors from data members are called (again in their definition order top-to-bottom)
- 3. Then the constructor initialization value for data members (basic types, references, constants) are used in the order described in that constructor (left-to-right)
- 4. Finally, the code of the constructor of the class is called.
- Destructors are called in a reverse way (starting from point 4 to point 1).

Tested with:

- cl.exe: 19.16.27030.1
- Params: /permissive- /GS- /analyze- /W3 /Zc:wchar_t /ZI /Gm- /Od /sdl /Fd"Debug\vc141.pdb" /Zc:inline /fp:precise /D "WIN32" /D "_DEBUG" /D "_CONSOLE" /D "_UNICODE" /D "UNICODE" /errorReport:prompt /WX- /Zc:forScope /RTCu /arch:IA32 /Gd /Oy- /MDd /FC /Fa"Debug\" /nologo /Fo"Debug\" /Fp"Debug\TestCpp.pch" /diagnostics:classic

```
class A
{
  public:
        int a1, a2, a3;
        void Set() { printf("A"); }
};
class B: public A
{
  public:
        int b1, b2;
        void Set() { printf("B"); }
};
void main()
{
        B b;
        b.Set();
}
```

- This code prints "B" on the screen. From the inheritance point of view, both A and B class have the same method called Set
- In this case it is said that class B hides method Set from class A

```
class A
{
  public:
        int a1, a2, a3;
        void Set() { printf("A"); }
};
class B: public A
{
  public:
        int b1, b2;
        void Set() { printf("B"); }
};
void main()
{
        B b;
        A* a = &b;
        a->Set();
}
```

- In this case, the code will print "A" on the screen, because we are using a pointer of type A*
- ❖ However, in reality, "a" pointer points to an object of type B → so the expected result should be that the product will print "B" and not "A"
- So what can we do to change this behavior?

```
class A
{
  public:
        int a1, a2, a3;
        virtual void Set() { printf("A"); }
};
  class B: public A
{
  public:
        int b1, b2;
        void Set() { printf("B"); }
};
  void main()
{
        B b;
        A* a = &b;
        a->Set();
}
```

- The solution is to use "virtual" keyword in from of a method definition
- If we do this, the program will print "B"
- In this case, it is said that class B <u>overrides</u> method Set from class A
- Using virtual keyword makes a method to be part of the instance!

Virtual methods can be used for:

- Polymorphism
- Memory deallocation (virtual destructor)
- Anti-debugging techniques

Polymorphism = the ability to access instances of different classes through the same interface. In particular to C++, this translates into the ability to automatically convert (cast) a pointer to a certain class to its base class.

App-1.cpp

- After the execution this code will print on the screen "Circle" and "Square".
- If we haven't uses virtual specifier, the program would have printed "Figure" twice!

Implements Function 1 In practice, in many cases, polymorphism Plugin 1 Function 2 is used to create a *plugin* or an add-on for an existing software. Function n Interface **Implements** Function 1 Function 1 Plugin 2 Function 2 Function 2 **Application** Function 3 Function n •••• **Implements** Function n Function 1 Plugin n Function 2 •••• Function n

In particular for C++ language, *virtual* specifier can be used as a specifier for destructors.

Let's analyze the following case:

App-1.cpp

```
class Figure {
    public: virtual void Draw() { printf("Figure"); }
   public: ~Figure() { printf("Delete Figure\n"); }
class Circle: public Figure {
    public: void Draw() { printf("Circle"); }
   public: ~Circle() { printf("Delete Circle"); }
};
class Square: public Figure {
    public: void Draw() { printf("Square"); }
   public: ~Square() { printf("Delete Square"); }
};
void main() {
      Figure *f[2];
      f[0] = new Circle();
      f[1] = new Square();
      for (int index = 0;index<2;index++)</pre>
            delete (f[index]);
```

- After this code gets executed, the following texts will be printed on the screen:
 - "Delete Figure".

 "Delete Figure".
- What would happen if both Circle and Square classes allocate some memory?

In particular for C++ language, *virtual* specifier can be used as a specifier for destructors.

Let's analyze the following case:

App-1.cpp

```
class Figure {
    public:_virtual_void Draw() { printf("Figure"); }
   public: virtual ~Figure() { printf("Delete Figure\n"); }
class Circle: public Figure {
    public: void Draw() { printf("Circle"); }
   public: ~Circle() { printf("Delete Circle"); }
};
class Square: public Figure {
    public: void Draw() { printf("Square"); }
   public: ~Square() { printf("Delete Square"); }
};
void main() {
      Figure *f[2];
      f[0] = new Circle();
      f[1] = new Square();
      for (int index = 0;index<2;index++)</pre>
            delete (f[index]);
```

- The solution is to declare de destructor as virtual. As a result, the destructor for actual class will be called, fallowed by the destructor of the base class
- The following text will be printed:Delete Circle

Delete Figure Delete Square Delete Figure

Let's analyze the following case:

App-1.cpp

```
class A
{
public:
    virtual bool Odd(int x) { return x % 2 == 0; }
};
class B : public A
{
public:
    virtual bool Odd(char x) { return x % 3 == 0; }
};
int main() {
    A* a = new B();
    printf("%d\n", a->Odd(3));
    return 0;
}
```

Odd is a virtual function - however, class B does not override it (as it uses char as the first parameter instead of int). As a result, class B will have 2 Odd methods and a->Odd will call the one with an int parameter. Upon execution, value false (0) is written to the screen.

Let's analyze the following case:

Odd is a virtual function - however, class B does not override it (as it uses char as the first parameter instead of int). As a result, class B will have 2 Odd methods and a->Odd will call the one with an int parameter. Upon execution, value false (0) is written to the screen.

Let's analyze the following case:

Assuming that, in reality, the intent was to override *Odd* method, than one way of making sure that this kind of mistakes will not happen is to use the *override* keyword (added with C++11 standard). As a result, this code will not compile as it is expected that method Odd to have the same signature!!!

Let's analyze the following case:

App-1.cpp

Now the code compiles and prints "1" (true) on the screen.

Let's consider the following code:

App-1.cpp

```
struct A {
    virtual bool Odd(int x) = 0;
};
struct B : public A {
    virtual bool Odd(int x) { return x % 2 == 0; }
};
struct C : public B {
    virtual bool Odd(int x) { return x % 3 == 0; }
};
int main() {
    A* a = new C();
    printf("%d\n", a->Odd(3));
    return 0;
}
```

- ► This program runs and prints value 1 (True) \rightarrow even if 3 is not an odd number.
- The reason why this could happen is that method *Odd* was overridden in class C (keep in mind that we have used *struct* in this example to show that the behavior is identical to the one from *class*).
- What can we do if we want to make sure that *Odd* method from class B can not be overridden?

Let's consider the following code:

```
App-1.cpp
struct A {
    virtual bool Odd(int x) = 0;
};
struct B : public A {
   virtual bool Odd(int x) final { return x % 2 == 0; }
};
struct C : public B {
    virtual bool Odd(int x) { return x % 3 == 0; }
};
                                  error C3248: 'B::Odd': function declared as 'final'
int main() {
                                          cannot be overridden by 'C::Odd'
   A* a = new C();
   printf("%d\n", a->Odd(3));
   return 0;
```

► The solution is to use the specifier *final* after the declaration of a virtual function. This tells the compiler that other classes that inherit current class can not **override** that method.

Let's consider the following code:

App-1.cpp

```
struct A {
    virtual bool Odd(int x) = 0;
};
struct B : public A {
    virtual bool Odd(int x) override final { return x % 2 == 0; }
};
struct C : public B {
};
int main() {
    A* a = new C();
    printf("%d\n", a->Odd(3));
    return 0;
}
```

- It is possible to use both *override* and *final* specifiers when declaring a method.
- In this case their meaning is:
 - override → The purpose of this method is to override the existing method from the base class (in this case, it overrides A::Odd)
 - \rightarrow Other classes that might inherit class B can not override this method.

Let's consider the following code:

- final specifier can also be used directly in the class/struct definition. In this case, it's meaning is that inheritance from class B is NOT possible.
- This code will not compile!

Let's analyze the following two programs. Their only difference is the usage of *virtual* in case of APP-2.

```
App-1.cpp

class A
{
  public:
        int a1, a2, a3;
        void Set() { printf("A"); }
};

void main()
{
        printf("%d",sizeof(A));
}
```

```
App-2.cpp

class A
{
  public:
        int a1, a2, a3;
        virtual void Set() { printf("A"); }
};
  void main()
{
        printf("%d", sizeof(A));
}
```

- * When executed, APP-1 will print "12" and App-2 will print "16" (for x86 architecture). If we run the same App-2 on x64 it will print "24"
- Why?

Using the virtual keyword will force the compiler to modify the structure of any class by adding another data member (a pointer to a list of pointers to a function). This pointer is called vfptr and if added is the first pointer in the class.

App-1.cpp

```
class A
{
  public:
        int a1, a2, a3;
        void Set() { printf("A"); }
};
void main()
{
        A a;
}
```

Memory

Using the virtual keyword will force the compiler to modify the structure of any class by adding another data member (a pointer to a list of pointers to a function). This pointer is called vfptr and if added is the first pointer in the class.

App-1.cpp

class A
{
 public:
 int a1, a2, a3;
 void Set() { printf("A"); }
};
 void main()
{
 A a;
}

Memory ... A::Set()

class.

Using the virtual keyword will force the compiler to modify the structure of any class by adding another data member (a pointer to a list of pointers to a function). This pointer is called vfptr and if added is the first pointer in the

class.

```
App-2.cpp

class A
{
  public:
        int a1, a2, a3;
        virtual void Set() { printf("A"); }
};
  void main()
{
        A a;
}
```

• Whenever a virtual method is added, the compiler needs to make certain that vfptr pointer is set correctly. As such, any constructor is modified to include the code that sets up the vfptr pointer. If no constructor is present, the default one will be created automatically.

```
App.cpp

class A
{
   public:
        int x, y;
        int Calcul() { return x+y; }
};
void main()
{
        A a;
        a.x = 1;
        a.y = 2;
}
```

In this case, there no default constructor defined and no need for the compiler to provide one automatically (e.g. virtual methods, const or reference data members, etc).

• Whenever a virtual method is added, the compiler needs to make certain that vfptr pointer is set correctly. As such, any constructor is modified to include the code that sets up the vfptr pointer. If no constructor is present, the default one will be created automatically.

```
Disasm
App.cpp
class A
                                          lea
                                                         ecx, [ebp-16]
public:
                                          call
                                                        A::A
     int x, y;
     int Calcul() { return x+y;
                                               a.x = 1;
     A() \{ x = y = 0; \}
                                                        dword ptr [ebp-16],1
                                          mov
                                               a.y = 2;
void main()
                                                        dword ptr [ebp-12],2
                                          mov
     a.x = 1:
     a.v = 2;
```

In this case, there is a constructor that will be called when "a" is created.

• Whenever a virtual method is added, the compiler needs to make certain that vfptr pointer is set correctly. As such, any constructor is modified to include the code that sets up the vfptr pointer. If no constructor is present, the default one will be created automatically

```
Disasm (A::A)
App.cpp
class A
public:
                                                    dword ptr [ebp-8],ecx // EBP-8=this
                                       mov
     int x, y;
     int Calcul() { return x+y; }
                                                    eax, dword ptr [ebp-8]
                                       mov
    A() \{ x = y = 0; \}
                                                    dword ptr [eax+4],0 // this->y = 0
                                       mov
                                                    ecx, dword ptr [ebp-8]
                                       mov
void main()
                                                    dword ptr [ecx],0 // this->x = 0
                                       mov
                                                    eax, dword ptr [ebp-8]
     A a:
                                       mov
     a.x = 1:
     a.y = 2;
                                       ret
```

❖ In this case, there is a default constructor and the code from the default constructor will be called when object "a" is created.

Whenever a virtual method is added, the compiler needs to make certain that vfptr pointer is set correctly. As such, any constructor is modified to include the code that sets up the vfptr pointer. If no constructor is present, the default one will be created automatically

```
Disasm
App.cpp
class A
                                          lea
                                                        ecx, [ebp-20]
public:
                                          call
                                                       A::A
     int x, y;
    virtual int Calcul() {return x+y;}
                                              a.x = 1;
                                                       dword ptr [ebp-16],1
                                          mov
void main()
                                              a.y = 2;
                                                       dword ptr [ebp-12],2
                                          mov
     a.x = 1:
     a.y = 2;
```

❖ In this case, even if no constructor is defined, the compiler will automatically create one to initialize the *vfptr* pointer (this is required because *Calcul* is a virtual method).

• Whenever a virtual method is added, the compiler needs to make certain that vfptr pointer is set correctly. As such, any constructor is modified to include the code that sets up the vfptr pointer. If no constructor is present, the default one will be created automatically

```
Disasm
App.cpp
class A
                                                    ecx, [ebp-20]
                                       lea
public:
                                                    A::A
                                       call
    int x, y;
    virtual int Calcul() {return x+y;}
};
                                                                ebp-16],1
           Disasm
void main()
                                                                ebp-12],2
    a.x = 1 \text{ MOV}
                                                                      Memory address where a list of
    a.y = 1 mov
                        dword ptr [ebp-8],ecx
                        eax, dword ptr [ebp-8]
                                                                      pointers to virtual functions is
                        dword ptr [eax], A-virtual-fnc-list
           mov
                                                                      (in this case only one method:
                        eax, dword ptr [ebp-8]
           mov
                                                                                   Calcul)
                        esp,ebp
           mov
           ret
```

• Whenever a virtual method is added, the compiler needs to make certain that vfptr pointer is set correctly. As such, any constructor is modified to include the code that sets up the vfptr pointer. If no constructor is present, the default one will be created automatically

```
App.cpp

class A
{
  public:
        int x, y;
        virtual int Calcul() {return x+y;}
        A() { x = y = 0; }
};
  void main()
{
        A a;
        a.x = 1;
        a.y = 2;
}
```

❖ If a constructor exists, it will be modified (in a similar manner to the change that is done for const/references data members).

• Whenever a virtual method is added, the compiler needs to make certain that vfptr pointer is set correctly. As such, any constructor is modified to include the code that sets up the vfptr pointer. If no constructor is present, the default one will be created automatically

```
App.cpp

class A
{
  public:
        int x, y;
        virtual int Calcul() {return x+y;}
        A() { x = y = 0; }
};
  void main()
{
        A a;
        a.x = 1;
        a.y = 2;
}
```

The code colored in blue is the code added by the compiler to initialize the vfptr pointer.

```
Disasm A::A
push
             ebp
             ebp, esp
mov
             dword ptr [ebp-8],ecx
mov
             eax, dword ptr [ebp-8]
mov
             dword ptr [eax],addr virt fnc
mov
             eax,dword ptr [ebp-8]
mov
             dword ptr [eax+8],0
mov
             ecx, dword ptr [ebp-8]
mov
             dword ptr [ecx+4],0
mov
             eax, dword ptr [ebp-8]
mov
             esp,ebp
mov
             ebp
pop
ret
```

The code added by the compiler to initialize the *vfptr* pointer will be added for every defined constructor.

```
class A
{
    public:
        int x, y;
        virtual int Calcul() {return x+y;}
        A() { x = y = 0; }
        A(const A& a) { x = a.x; y = a.y; }
};
void main()
{
        A a;
        A a;
        A a2 = a;
}
```

In this case the code for *vfptr* initialization will be added for both the default constructor and the copy constructor.

* However, in case of the assignment operator the compiler will not add any special code to initialize the vfptr pointer.

```
class A
{
public:
    int x, y;
    virtual int Calcul() {return x+y;}
    A() { x = y = 0; }
    A& operator = (A &a) { x = a.x; y = a.y; return *this;}
};
void main()
{
    A a;
    A a2;
    a2 = a;
}
```

* A virtual method is called using its reference from the *vfptr* table only if the object is a pointer.

```
Disasm
App.cpp
class A
                                             A a;
                                                      ecx,[a]
                                        lea
public:
                                        call
                                                      A::A
     int x, y;
     virtual int Calcul() {return x+y;}
                                             a.x = 1;
     A() \{ x = y = 0; \}
                                                      dword ptr [ebp-10h],1
                                        mov
};
                                             a.y = 2;
void main()
                                                      dword ptr [ebp-0Ch],2
                                        mov
                                             a.Calcul();
     A a;
     a.x = 1;
                                        lea
                                                      ecx,[a]
                                        call
                                                      A::Calcul
     a.Calcul()
```

In this case, even if *Calcul* method is *virtual* as it called directly with an object, the compiler will not generate code that will find out its address from the *vfptr* table (it will use the method *Calcul* exact address).

* A virtual method is called using its reference from the *vfptr* table only if the object is a pointer.

call

eax

```
App.cpp

class A
{
   public:
        int x, y;
        virtual int Calcul() {return x+y;}
        A() { x = y = 0; }
};
void main()
{
        A a;
        a.x = 1;
        a.y = 2;
        A* a2 = &a;
        a2->Calcul();
}
```

In this case vfptr is used to find out Calcul method address.

```
Disasm
     A a;
lea
            ecx,[a]
call
            A::A
     a.x = 1:
            dword ptr [ebp-10h],1
mov
     a.v = 2;
            dword ptr [ebp-0Ch],2
mov
    A^* a2 = &a;
            eax,[a]
lea
            dword ptr [a2],eax
mov
     a2->Calcul();
                                         EAX = address of a2
            eax, dword ptr [a2]
mov

                                                 int (*Calcul) ();
public:
                                           };
                                           class A {
     int x;
     virtual int Calcul() {return 0;}
                                           public:
     A() \{ x = 0; \}
                                                 A VirtualFunctions *vfPtr;
};
void main()
                                                 int A_Calcul() { return 0; }
     A a;
     a.x = 1;
     a.y = 2;
     A* a2 = &a;
     a2->Calcul();
```

Pseudo C/C++ Code App.cpp class A struct A_VirtualFunctions { int (*Calcul) (); public: **}**; class A { int x: virtual int Calcul() {return 0;} public: A VirtualFunctions *vfPtr; **}**; int x; void main() int A_Calcul() { return 0; } A a; a.x = 1;a.y = 2;A* a2 = &a;A_VirtualFunctions Global_A_vfPtr; a2->Calcul(); Global A vfPtr.Calcul = &A::A Calcul;

Pseudo C/C++ Code App.cpp class A struct A_VirtualFunctions { int (*Calcul) (); public: **}**; class A { int x; virtual int Calcul() {return 0;} public: A VirtualFunctions *vfPtr; $A() \{ x = 0; \}$ **}**; int x; void main() int A Calcul() { return 0; } A() { A a; a.x = 1;x = 0; a.y = 2;A* a2 = &a;A_VirtualFunctions Global_A_vfPtr; a2->Calcul(); Global A vfPtr.Calcul = &A::A Calcul;

Pseudo C/C++ Code App.cpp class A struct A_VirtualFunctions { int (*Calcul) (); public: **}**; class A { virtual int Calcul() {return 0;} public: A VirtualFunctions *vfPtr; **}**; int x; void main() int A_Calcul() { return 0; } vfPtr = &Global_A_vfPtr; A a; a.x = 1; $X = \emptyset;$ a.y = 2;A* a2 = &a;A_VirtualFunctions Global_A_vfPtr; a2->Calcul(); Global A vfPtr.Calcul = &A::A Calcul;

Pseudo C/C++ Code App.cpp class A struct A_VirtualFunctions { int (*Calcul) (); **}**; public: class A { int x; virtual int Calcul() {return 0;} public: A VirtualFunctions *vfPtr; $A() \{ x = 0; \}$ int x; void main() int A_Calcul() { return 0; } **A()** { vfPtr = &Global_A_vfPtr; A a; a.x = 1;x = 0; a.y = 2;A* a2 = &a;A VirtualFunctions Global A vfPtr; a2->Calcul(); Global_A_vfPtr.Calcul = &A::A_Calcul; void main() A a; a.x = 1;a.y = 2;A* a2 = &a;

App.cpp

```
class A
{
public:
    int x;
    virtual int Calcul() {return 0;}
    A() { x = 0; }
};
void main()
{
    A a;
    a.x = 1;
    a.y = 2;
    A* a2 = &a:
    a2->Calcul();
}
```

Pseudo C/C++ Code

```
struct A_VirtualFunctions {
      int (*Calcul) ();
};
class A {
public:
      A VirtualFunctions *vfPtr;
      int x;
      int A_Calcul() { return 0; }
      A() {
            vfPtr = &Global_A_vfPtr;
            x = 0;
A_VirtualFunctions Global_A_vfPtr;
Global A vfPtr.Calcul = &A::A Calcul;
void main()
      A a;
      a.x = 1;
      a.y = 2;
      A* a2 = &a:
      a2->vfPtr->Calcul();
```

* Keep in mind the *vfptr* is just a pointer. As such, it can be changed during execution

App.cpp

```
class A
public:
      int x;
      virtual void Print() { printf("A"); }
class B
public:
      int x:
      virtual void Print() { printf("B"); }
void main()
      A a;
      B b;
      A* a2 = &a;
      a.Print();
      a2->Print();
```

This code will print "AA" on the screen. First time when method Print is called directly ("a.Print()"), second time when method Print is called using the vfptr pointer ("a2->Print()")

* Keep in mind the **vfptr** is just a pointer. As such, it can be changed during execution

App.cpp

```
class A
public:
      int x;
      virtual void Print() { printf("A"); }
class B
public:
      int x:
      virtual void Print() { printf("B"); }
void main()
      A a;
      memcpy(&a, &b, sizeof(void*));
     A^* a2 = &a;
      a.Print();
      a2->Print();
```

This code will however print "AB". Using memcpy function allow us to overwrite the actual vfptr-ul of object "a" with the one from object "b". As method Print has the same signature in both classes (A and B) the result will be "AB"

* Keep in mind the *vfptr* is just a pointer. As such, it can be changed during execution

App.cpp

```
class A
public:
      int x;
      virtual void Print() { printf("A"); }
class B
public:
      int x:
      virtual void Print() { printf("B"); }
void main()
      A a;
      B b;
      memcpy(&a, &b, sizeof(void*));
      A* a2 = &a;
      A = (*a2);
      A *a4 = &a3;
      a4->Print();
```

- Every constructor called will set the *vfptr* to its correct value. In this case, "A a3=(*a2)" will call the copy constructor for class A and will set the *vfptr* for local variable a3 correctly.
- As a result this code will print "A" on the screen, even if "a2" has the vfptr of "b"

* A virtual function can be overwritten in the derived class.

App.cpp

```
class A
public:
      int x, y;
      virtual int Suma() { return x + y; }
      virtual int Diferenta() { return x - y; }
      virtual int Produs() { return x*y; }
};
class B : public A
public:
      int Suma() { return 1; }
};
void main()
      B b;
      b.x = 1;
      b.y = 2;
      A* a;
      a = \&b;
      int x = a->Suma();
```

- In this case, "x" will be 1 as "a" is in fact an object of type "b" that has overwrite method "Suma"
- For the rest of the methods (Diferenta and Produs) the behavior will be identical to the one from the base class (A).

A derived class can also add other (new) virtual methods.

```
App.cpp
class A
public:
      int x, y;
      virtual int Suma() { return x + y; }
      virtual int Diferenta() { return x - y; }
      virtual int Produs() { return x*y; }
};
class B : public A
public:
     int Suma() { return 1: }
     virtual int Modul() { return 0; }
};
void main()
```

- In this case, class B also have a new virtual method called "Module") that is not present on class A.
- This means that any class that will be derived from B will have this method as well.

VFTable for class A

Let's analyze the following code:

App.cpp

```
class A
{
  public:
        int a1, a2;
        virtual A* clone() { return new A(); }
};
class B : public A
{
  public:
        int b1, b2;
        virtual A* clone() { return new B(); }
};
void main()
{
        B *b = new B();
        B *ptrB;
        ptrB = b->clone();
}
```

This code will not compile. However, in reality "b->clone()" returns an object of type B so it should work.

error C2440: '=': cannot convert from 'A *' to 'B *'
note: Cast from base to derived requires dynamic_cast
or static_cas

Let's analyze the following code:

App.cpp

```
class A
{
  public:
        int a1, a2;
        virtual A* clone() { return new A(); }
};
class B : public A
{
  public:
        int b1, b2;
        virtual A* clone() { return new B(); }
};
void main()
{
        B *b = new B();
        B *ptrB;
        ptrB = b->clone();
}
```

• We have two solutions for this problem:

Let's analyze the following code:

```
App.cpp
class A
public:
      int a1, a2;
      virtual A* clone() { return new A(); }
class B : public A
public:
      int b1, b2;
      virtual A* clone() { return new B(); }
void main()
      B *b = new B
      ptrB = (B*) b->clone();
```

- We have two solutions for this problem:
- Use an explicit cast and convert the pointer from A* to B*

Let's analyze the following code:

- We have two solutions for this problem:
- 1. Use an explicit cast and convert the pointer from **A*** to **B***
- 2. Use <u>covariance</u>. This means that we can modify the return type of the method *clone* in class *B* to return a *B* pointer* instead of an *A* pointer*.

Let's analyze the following code:

App.cpp

```
class A
public:
      int a1, a2;
      virtual A* clone() { return new A(); }
class B : public A
public:
      int b1, b2;
      virtual B* clone() { return new B(); }
void main()
      B *b = new B();
      B *ptrB;
      ptrB = b->clone();
      A *a = (A*)b;
      ptrB = (B*)a->clone();
```

- We have two solutions for this problem:
- Use an explicit cast and convert the pointer from A* to B*
- 2. Use <u>covariance</u>. This means that we can modify the return type of the method *clone* in class *B* to return a *B* pointer* instead of an *A* pointer*.

Covariance is related to the pointer type. In this case, even if the compiler calls "B::clone", the expected value is A^* (specific to a A^* pointer that is "a" \rightarrow "A::clone")

Let's analyze the following code:

App.cpp

```
class A
public:
      int a1, a2;
      virtual A* clone() { return new A(); }
class B : public A
public:
      int b1, b2;
      virtual B* clone() { return new B(); }
void main()
      B *b = new B();
      B *ptrB;
      ptrB = b->clone();
      A *a = (A*)b;
      ptrB = a->clone();
```

- We have two solutions for this problem:
- 1. Use an explicit cast and convert the pointer from **A*** to **B***
- 2. Use <u>covariance</u>. This means that we can modify the return type of the method *clone* in class *B* to return a *B* pointer* instead of an *A* pointer*.

That is why this code will **NOT** compile, as the result for *a->clone* is *A** and not *B**. During execution, "*B::clone*" will be call nevertheless.

Let's analyze the following code:

App.cpp

```
class A
{
  public:
        int a1, a2;
        virtual A* clone() { return new A(); }
};
class B : public A
{
  public:
        int b1, b2;
        virtual int* clone() { return new int(); }
};
void main()
{
        error C2555: 'B::clone': over the clone of the clone of
```

This code will not compile. The return type for virtual functions can be changed, but only to a type that is derived from the return type of the virtual method described in the base class. In this case, int* is not derived from A*

error C2555: 'B::clone': overriding virtual function return type differs and is not covariant from 'A::clone'

- In C++ we can define an virtual method without a body (it is called a pure virtual method and it is defined by adding "=0" at the end of its definition).
- If a class contains a pure virtual method, that class is an abstract class (a class that can not be instantiated). In other languages this concept is <u>similar</u> to the concept of an interface.
- Having a pure virtual method forces the one that implements a derived class to implement that method as well if he/she would like to create an instance from the newly created class.

```
App.cpp

class A
{
public:
    int a1, a2, a3;
    virtual void Set() = 0;
};

void main()
{
    A a;
}

abstract class

error C2259: 'A': cannot instantiate abstract class
note: due to following members:
    note: 'void A::Set(void)': is abstract
    note: see declaration of 'A::Set'
```

In C++ we can define an virtual method without a body (it is called a pure virtual method and it is defined by adding "=0" at the end of its definition).

App.cpp

```
class A
{
  public:
        int a1, a2, a3;
        virtual void Set() = 0;
};
class B: A
{
  public:
        int a1, a2, a3;
        void Set(){... };
}
void main()
{
        B b;
}
```

- This code will compile because class B has an implementation for method Set
- In order to be able to create an instance of a class, all of its pure virtual methods (defined in that class or obtained via inheritance) MUST be implemented!

In C++ we can define an virtual method without a body (it is called a pure virtual method and it is defined by adding "=0" at the end of its definition).

App.cpp class A { public: int a1, a2, a3; virtual void Set() = 0; }; class B: A { public: int a1, a2, a3; void Set(){...}; } void main() { B b: A* a; }

This code will however compile. It is possible (and recommended whenever working with polymorphism) to create a pointer towards an abstract class (in this case an A* pointer).

- Other languages (such as Java or C#) have a similar concept called interface (primarily used in these languages to avoid multiple inheritance).
- interfaces are however different from an abstract class. An interface CAN NOT have data members, or methods that are not pure virtual. An abstract class is a class that has at least one pure virtual method. An abstract class can have methods, constructors, destructor or data members.
- In C++ it is often easier to use *struct* instead of class to describe in interface due to the fact that the default access modifier is *public*
- Cl.exe (Microsoft) has a keyword (__interface) that works like an interface (allows you to create on). However, this is not part of the standard.

```
class A
{
public:
   int a1,a2,a3;
};
```

```
sizeof(A) = 12
```

```
class B: public A
{
public:
  int b1,b2
};
```

<pre>sizeof(B)</pre>	=	20
----------------------	---	----

Offset	Field	C1	C2
+ 0	A::a1

+ 8	A::a3		B
+ 12	B::b1		
+ 16	B::b2		

```
class A
public:
  int a1,a2,a3;
                                  Offset
                                          Field
                                                     C1
};
                                      + 0 A::a1
sizeof(A) = 12
                                      + 4+ A::a2
                                      + 8 A::a3
class B: public A
                                     + 12 | B::b1
                                     + 16 | B::b2
public:
  int b1,b2
};
```

sizeof(B) = 20

C2

```
class A
{
public:
   int a1,a2,a3;
};
```

```
sizeof(A) = 12
```

```
class B: public A
{
public:
   int b1,b2
};
```

sizeof(B) = 20

Offset	Field	C1	C2
+ 0	A::a1		
+ 4	A::a2	A	
+ 8	A::a3		B
+ 12	B::b1		
+ 16	B::b2		

```
class A
{
  public:
    int a1,a2,a3;
  };

sizeof(A) = 12

+ 4	B::b2	В	•	
+ 8	A::a1		Δ	
+ 12	A::a2			
+ 16	A::a3)
+20	C::c1			
+24	C::c2			

warning C4584: 'C': base-class 'A' is already a baseclass of 'B'.

* Multiple inheritance can create ambiguous situations. For example, in this

case the fields from class A are copied twice in class C.

App.cpp

```
class A
public:
     int a1, a2, a3;
class B: public A
public:
     int b1, b2;
class C : public A, public B
public:
     int c1, c2;
void main()
```

Offset	Field	C1	C2	C 3
+0	A::a1			
+4	A::a2	A		
+8	A::a3			
+12	B::A::a1			
+16	B::A::a2	B::A		
+20	B::A::a3		B	
+24	B::b1			
+28	B::b2			
+32	C::c1			
+36	C::c2			

* Multiple inheritance can create ambiguous situations. For example, in this case the fields from class A are copied twice in class C.

App.cpp

```
class A {
public:
        int a1, a2, a3;
};
class B: public A {
public:
        int b1, b2;
};
class C : public A, public B {
public:
        int c1, c2;
};
void main()
{
        C :
        C.a1 = 10;
}
```

This is an ambiguous case. "c.a1 = 10" can refer to the member "a1" from the direct inheritance of class A, or the member "a1" from the direct inheritance of class B that in terms inherits class A.

This code will NOT compile !!!

* Multiple inheritance can create ambiguous situations. For example, in this case the fields from class *A* are copied twice in class *C*.

App.cpp

```
class A {
public:
    int a1, a2, a3;
};
class B: public A {
public:
    int b1, b2;
};
class C : public A, public B {
public:
    int c1, c2;
};
void main()
{
        C c;
        c.A::a1 = 10;
        c.B::A::a1 = 20;
}
```

- The solution is to describe any field/data member using its full scope. For example:
 - "c.A::a1" means data member "a1" from the direct inheritance of "A" in class "C"
 - "c.B::A::a1" means data member "a1" from the inheritance of "A" in class "B" that is directly inherit by class "C"
- What can we do if we want to have only one copy of the fields from class "A" in our object?
- This problem is also known as the "Diamond Problem"

* Multiple inheritance can create ambiguous situations. For example, in this case the fields from class *A* are copied twice in class *C*.

App.cpp class A { public: int a1, a2, a3; class B: public virtual public: int b1, b2; class C : public virtual A, public B { public: **int** c1, c2; void main() C c; c.a1 = 10;c.a2 = 20;

- One solution to this problem is to use the virtual specifier when deriving from a class. In this case, class "A" is inherit virtually (meaning that its fields must be added once).
- For this code to work, both "C" and "B" class need to inherit class "A" using virtual keyword.

* Just like in the case of virtual methods, if no constructor is present one will be created by the compiler. However, this constructor is a little bit different than the others (as it has one parameter of type bool).

```
Disasm
App.cpp
class A {
public:
                                      push
                                                                           TRUE
     int a1, a2, a3;
                                      lea
                                                    ecx,[c]
class B: public virtual A {
                                      call
                                                    C::C
public:
                                          c.a1 = 10;
     int b1, b2;
                                                    eax, dword ptr [c]
                                      mov
                                                    ecx, dword ptr [eax+4]
class C : public virtual A public B {
                                      mov
public:
                                                   dword ptr [c+ecx],10
                                      mov
     int c1, c2;
                                          c.b1 = 20;
                                                    dword ptr [c+20],20
                                      mov
void main()
```

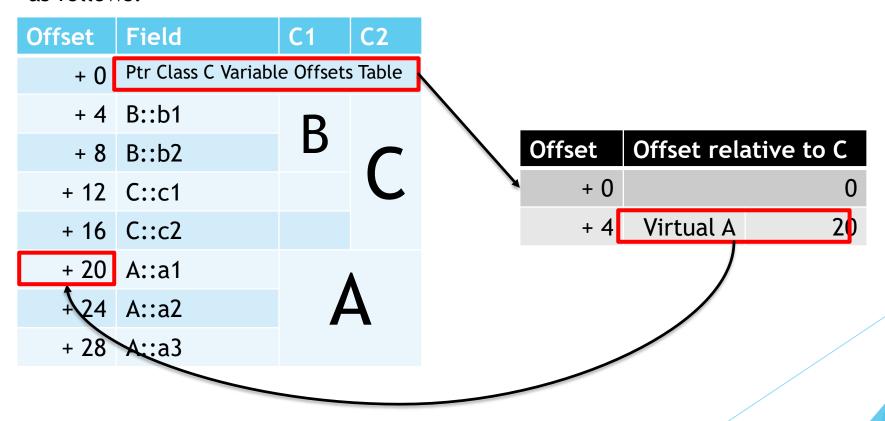

c.a1 = 10; c.b1 = 20;

The first parameter, tells the constructor if a special table with indexes needs to be created or not!

App.cpp class A { public: int a1, a2, a3; class B: public virtual A { public: int b1, b2; class C : public virtual A, public B ≱ public: **int** c1, c2; void main() c.a1 = 10: c.b1 = 20;

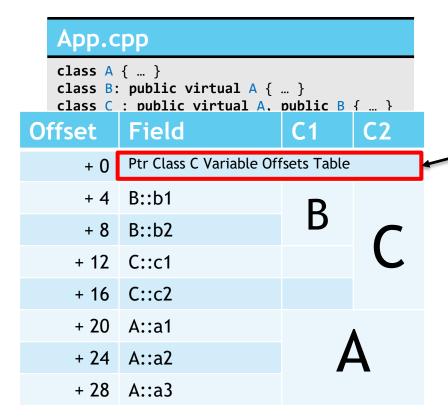

```
Disasm C::C
     push
                 ebp
    mov
                 ebp,esp
                 dword ptr [this],ecx
    mov
                 dword ptr [ebp+8],0
     cmp
    jе
                 DONT SET VAR PTR
                 eax,dword ptr [this]
    mov
                 dword ptr [eax],addr index
    mov
DONT SET VAR PTR:
     push
                 ecx,dword ptr [this]
     mov
    call
                 B::B
                 eax, dword ptr [this]
    mov
                 esp,ebp
    mov
                 ebp
     pop
     ret
```

Once the constructor is called, an object that has virtual inheritance will look as follows:

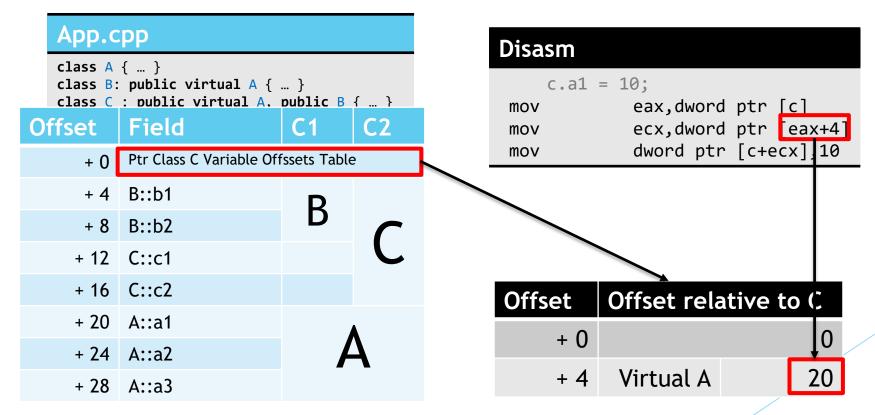

* Accessing a data member / field that benefits from the *virtual* inheritance, is done in 3 steps (not in one) in the following way:

In the first step, EAX register gets the pointer to the table where offstes of data member/fields from A class are stored

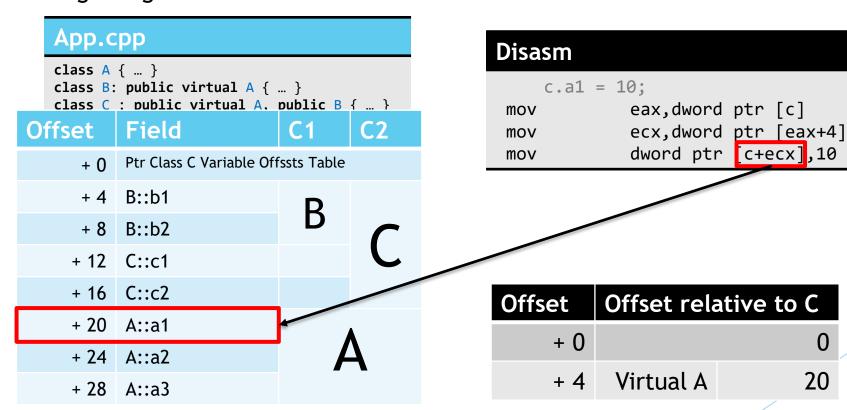

Second step - ECX gets the value from the second index in that table (+4), more exactly value 20 (that reflects the offset of "A" from the beginning of "C")

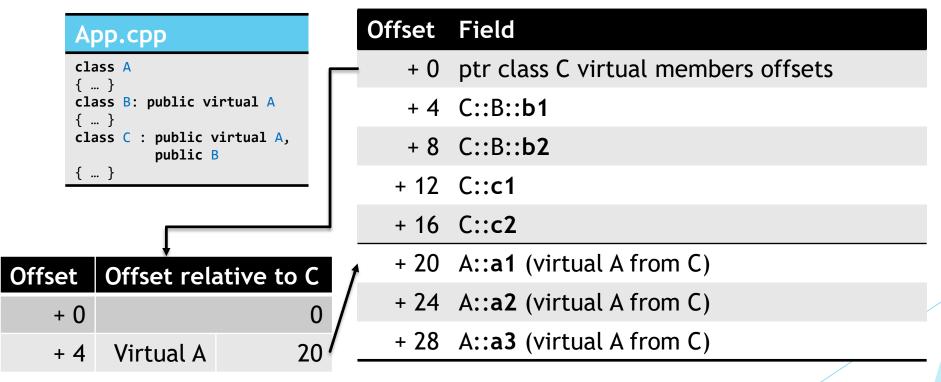

20

Last step, we use "ECX" register as an offset to access A::a1 from the beginning of local variable "c".

Fields/Data members that are obtained via virtual inheritance are usually added at the end of the class alignment.

❖ If we use virtual inheritance when deriving "C" from "B" (in addition to the usage of virtual inheritance for class "A") we will obtain the following alignment:

App.cpp
<pre>class A { } class B: public virtual A { } class C : public virtual A,</pre>
<pre>public virtual B { }</pre>

Offset	Offset relative to C		
+ 0		0	
+ 4	Virtual A	12	
+ 8	Virtual B	24	

	0661	
	Offset	Field
	+ 0	ptr class C virtual members offsets
	+ 4	C::c1
	+ 8	C::c2
1	+ 12	A::a1 (virtual A from C)
/	+ 16	A::a2 (virtual A from C)
	+ 20	A::a3 (virtual A from C)
4	+ 24	ptr class B virtual members offsets
	+ 28	B::b1 (virtual B from C)
	+ 32	B::b2 (virtual B from C)

Offset Field

❖ In case of the index table for class "B", the offset "-12" refers to the position of "A" class (also obtain via virtual inheritance) relative to B with respect to C class (24 (offset of B) - 12 = 12 (offset of A))

+ 0 ptr class C virtual members offsets

<pre>class B: public virtual A { }</pre>		+ 4	C::c1	
class C : public virtual A, public virtual B		+ 8	C::c2	
{ }		+ 12	A::a1 (virtual A from C)	
			+ 16	A::a2 (virtual A from C)
Offset	Offset rela	ative la B	+ 20	A::a3 (virtual A from C)
+ (+ 24	ptr class B virtual members offsets
+ 4		-12	+ 28	B::b1 (virtual B from C)
		-	+ 32	B::b2 (virtual B from C)

If we make only the inheritance of B from C to be virtual, the memory alignment is as follows:

Offset	Offset relative la C	
+ 0		-12
+ 4	Virtual B	12

Offset	Field
+ 0	A::a1
+ 4	A::a1
+ 8	A::a3
+ 12	ptr class C virtual members offsets
+ 16	C::c1
+ 20	C::c2
+ 24	B::A::a1
+ 28	B::A::a2
+ 32	B::A::a3
+ 36	B::b1
+ 40	B:: b2

If we make only the inheritance of B from C to be virtual, the memory alignment is as follows:

Offset	Offset relative la C		
+ 0		-12	
+ 4	Virtual B	12	

```
Offset
        Field
    + 0 A::a1
    + 4 A::a1
    + 8 A::a3
   + 12 ptr class C virtual members offsets
   + 16 C::c1
    First index (+0 offset, value -12) represents the
  offset of object C relative to the table of indexes).
     It is usually 0 (as this table is the first entry),
      however in this case it is a negative value.
   + 32 B::A::a3
   + 36 B::b1
   + 40 B::b2
```

If we make only the inheritance of B from C to be virtual, the memory alignment is as follows:

App.cpp class A { ... } class B: public A { ... } class C : public A, public virtual B { ... }

Offset	Field
+ 0	A::a1
+ 4	A::a1
+ 8	A::a3
+ 12	ptr class C virtual members offsets
+ 16	C::c1
+ 20	C::c2

Offset Offset relative la C
+ 0 -12
+ 4 Virtual B 12

The second offset (+4, value +12) reflects the position of B relative to the offset of the index table (12+12=24).

+ 30 0..01

+ 40 B::b2

Q & A
